## Description

This package implements the small-sample degrees of freedom adjustment discussed in Imbens and Kolesár [2016]. The implementation can handle models with fixed effects, and cases where the number of observations or clusters is large <sup>1</sup>.

```
library(dfadjust)
options(digits = 3)
```

To give some examples, let us construct an artificial dataset with 11 clusters

Let us first run a regression of y on x1. This is a case where in spite of moderate data size, the effective number of observations is small since there are only three treated units:

```
r1 <- lm(y ~ x1, data = d1)

## No clustering
dfadjustSE(r1)

#>

#> Coefficients:

#> Estimate HC1 se HC2 se Adj. se df p-value

#> (Intercept) 0.00266 0.0311 0.031 0.0311 996.00 0.932

#> x1 0.12940 0.8892 1.088 2.3743 2.01 0.957
```

Now consider a cluster-robust regression of y on x2. There are only 3 treated clusters, so the effective number of observations is again small:

```
r1 <- lm(y ~ x2, data = d1)
# Default Imbens-Kolesár method
dfadjustSE(r1, clustervar = d1$cl)</pre>
```

<sup>&</sup>lt;sup>1</sup>We thank Ulrich Müller for suggesting to us the lemma below

```
#> Coefficients:

#> Estimate HC1 se HC2 se Adj. se df p-value

#> (Intercept) -0.0236 0.0135 0.0169 0.0222 4.94 0.288

#> x2 0.1778 0.0530 0.0621 0.1157 2.43 0.124

# Bell-McCaffrey method

dfadjustSE(r1, clustervar = d1$cl, IK = FALSE)

#>

#> Coefficients:

#> Estimate HC1 se HC2 se Adj. se df p-value

#> (Intercept) -0.0236 0.0135 0.0169 0.0316 2.42 0.4547

#> x2 0.1778 0.0530 0.0621 0.1076 2.70 0.0983
```

Now, let us run a regression of y on x3, with fixed effects. Since we're only interested in x3, we specify that we only want inference on the second element:

Finally, an example in which the clusters are large. We have 500,000 observations:

```
d2 <- do.call("rbind", replicate(500, d1, simplify = FALSE))</pre>
d2$y <- rnorm(length(d2$y))</pre>
r2 \leftarrow lm(y \sim x2, data = d2)
summary(r2)
#>
#> Call:
\# lm(formula = y ~ x2, data = d2)
#>
#> Residuals:
#> Min 1Q Median 3Q
                                Max
#> -5.073 -0.675 0.000 0.675 4.789
#>
#> Coefficients:
#>
               Estimate Std. Error t value Pr(>|t|)
#> (Intercept) -0.000991 0.001535 -0.65 0.52
#> x2
          -0.003590 0.003963 -0.91
                                               0.37
#>
```

```
#> Residual standard error: 1 on 499998 degrees of freedom
#> Multiple R-squared: 1.64e-06, Adjusted R-squared:
#> F-statistic: 0.821 on 1 and 5e+05 DF, p-value: 0.365

### **Methods**

This section describes the implementation of the Imbens and Kolesár [2016] and Bell and McCaffrey [2002] degrees of freedom adjustments.

There are S clusters, and we observe  $n_s$  observations in cluster s, for a total of  $n = \sum_{s=1}^{S} n_s$  observations. We handle the case with independent observations by letting each observation be in its own cluster, with S = n. Consider the linear regression of a scalar outcome  $Y_i$  onto a p-vector of regressors  $X_i$ ,

$$Y_i = X_i'\beta + u_i, \qquad E[u_i \mid X_i] = 0.$$

We're interested in inference on  $\ell'\beta$  for some fixed vector  $\ell \in \mathbb{R}^p$ . Let X, u, and Y denote the design matrix, and error and outcome vectors, respectively. For any  $n \times k$  matrix M, let  $M_s$  denote the  $n_s \times k$  block corresponding to cluster s, so that, for instance,  $Y_s$  corresponds to the outcome vector in cluster s. For a positive semi-definite matrix M, let  $M^{1/2}$  be a matrix satisfying  $M^{1/2}M^{1/2} = M$ , such as its symmetric square root or its Cholesky decomposition.

Assume that

$$E[u_s u_s' \mid X] = \Omega_s$$
, and  $E[u_s u_t' \mid X] = 0$  if  $s \neq t$ .

Denote the conditional variance matrix of u by  $\Omega$ , so that  $\Omega_s$  is the block of  $\Omega$  corresponding to cluster s. We estimate  $\ell'\beta$  using OLS. In R, the OLS estimator is computed via a QR decomposition, X = QR, where Q'Q = I and R is upper-triangular, so we can write the estimator as

$$\ell'\hat{\beta} = \ell'\left(\sum_s X_s'X_s\right)^{-1} \sum_s X_sY_s = \tilde{\ell}'\sum_s Q_s'Y_s, \qquad \tilde{\ell} = R^{-1'}\ell.$$

It has variance

$$V := \operatorname{var}(\ell'\hat{\beta} \mid X) = \ell' \left( X'X \right)^{-1} \sum_{s} X'_{s} \Omega_{s} X_{s} \left( X'X \right)^{-1} \ell = \tilde{\ell}' \sum_{s} Q'_{s} \Omega_{s} Q_{s} \tilde{\ell}.$$

#### Variance estimate

We estimate *V* using a variance estimator that generalizes the HC2 variance estimator to clustering. Relative to the LZ2 estimator described in Imbens and Kolesár [2016], we use a slight modification that allows for fixed effects:

$$\hat{V} = \ell'(X'X)^{-1} \sum_{s} X'_{s} A_{s} \hat{u}_{s} \hat{u}'_{s} A'_{s} X_{s} (X'X)^{-1} \ell = \ell' R^{-1} \sum_{s} Q'_{s} A_{s} \hat{u}_{s} \hat{u}'_{s} A'_{s} Q_{s} R'^{-1} \ell = \sum_{s=1}^{S} (\hat{u}'_{s} a_{s})^{2},$$

where

$$\hat{u}_s := Y_s - X_s \hat{\beta} = u_s - O_s O'u, \qquad a_s = A'_s O_s \tilde{\ell},$$

and the matrix  $A_s$  is given by the symmetric square root of the inverse of  $I - Q_s Q_s'$ , or else its pseudo-inverse if it is singular, as is the case, for example, if X contains fixed effects. We do not need to insist on  $I - Q_s Q_s'$  to be invertible, since, using the identity

$$\hat{V} = u \sum_{s} (I - QQ')'_s a_s a'_s (I - QQ')_s u,$$

one can verify by simple algebra that a sufficient condition for  $\hat{V}$  to be unbiased under homoskedasticity is that  $Q'_sA_s(I-Q_sQ'_s)A_sQ_s=Q'_sQ_s$  (see, for example, Pustejovsky and Tipton [2018], for details).

If the observations are independent, the vector of leverages  $(Q_1'Q_1,\ldots,Q_n'Q_n)$  can be computed directly using the stats::hatvalues function. In this case, use this function to compute  $A_i = 1/\sqrt{1-Q_i'Q_i}$  directly, and we then compute  $a_i = A_iQ_i'\tilde{\ell}$  using vector operations. For the case with clustering, computing the spectral decomposition of  $I-Q_sQ_s'$  can be expensive or even infeasible if the cluster size  $n_s$  is large. We therefore use the following result, suggested to us by Ulrich Müller, allows us to compute  $a_s$  by computing a spectral decomposition of a  $p \times p$  matrix.

• Let  $Q_s'Q_s = \sum_{i=1}^p \lambda_{is}r_{is}r_{is}'$  be the spectral decomposition of  $Q_s'Q_s$ . Then  $A_s = \sum_{i: \lambda_i \neq 1} (1 - \lambda_i)^{-1/2}Q_sr_{is}r_{is}'Q_{s}'$  satisfies  $A_s(I - Q_sQ_s')A_s = I$ .

This follows from the fact that  $I - Q_s Q_s'$  has eigenvalues  $1 - \lambda_{is}$  and eigenvectors  $Q_s r_{is}$ , and hence its pseudoinverse is  $\sum_{i: \lambda_i \neq 1} (1 - \lambda_i)^{-1} Q_s r_{is} r_{is}' Q_s'$ .

Using the lemma, we can compute  $a_s$  efficiently as:

$$a_s = \sum_{i: \lambda_i \neq 1} (1 - \lambda_i)^{-1/2} Q_s r_{is} r'_{is} Q'_s Q_s \tilde{\ell} = Q_s D_s \tilde{\ell}, \qquad D_s = \sum_{i: \lambda_i \neq 1} \lambda_i (1 - \lambda_i)^{-1/2} r_{is} r'_{is}.$$

#### Degrees of freedom correction

Let *G* be an  $n \times S$  matrix with columns  $(I - QQ')'_s a_s$ . Then the Bell and McCaffrey [2002] adjustment sets the degrees of freedom to

$$f_{\rm BM} = \frac{\operatorname{tr}(G'G)^2}{\operatorname{tr}((G'G)^2)}.$$

Since  $(G'G)_{st} = a'_s(I - QQ')_s(I - QQ)'_ta_t = a_s(\mathbb{1}\{s=t\} - Q_sQ'_t)a_t$ , the matrix G'G can be efficiently computed as

$$G'G = \operatorname{diag}(a'_s a_s) - BB'$$
  $B_{sk} = a'_s Q_{sk}$ .

Note that *B* is an  $S \times p$  matrix, so that computing the degrees of freedom adjustment only involves  $p \times p$  matrices:

$$f_{\rm BM} = \frac{(\sum_s a_s' a_s - \sum_{s,k} B_{sk}^2)^2}{\sum_s (a_s' a_s)^2 - 2\sum_{s,k} (a_s' a_s) B_{sk}^2 + \sum_{s,t} (B_s' B_t)^2}.$$

If the observations are independent, we compute B directly as B < -a\*Q, and since  $a_i$  is a scalar, we have

$$f_{\text{BM}} = \frac{(\sum_{i} a_{i}^{2} - \sum_{sk} B_{sk}^{2})^{2}}{\sum_{i} a_{i}^{4} - 2\sum_{i} a_{i}^{2} B_{i}' B_{i} + \sum_{i,j} (B_{i}' B_{j})^{2}}.$$

The Imbens and Kolesár [2016] degrees of freedom adjustment instead sets

$$f_{IK} = \frac{\operatorname{tr}(G'\hat{\Omega}G)^2}{\operatorname{tr}((G'\hat{\Omega}G)^2)},$$

where  $\hat{\Omega}$  is an estimate of the Moulton [1986] model of the covariance matrix, under which  $\Omega_s = \sigma_\epsilon^2 I_{n_s} + \rho \iota_{n_s} \iota_{n_s}'$ . Using simple algebra, one can show that in this case,

$$G'\Omega G = \sigma_{\epsilon}^2 \operatorname{diag}(a_s'a_s) - \sigma_{\epsilon}^2 BB' + \rho(D - BF')(D - BF')',$$

where

$$F_{sk} = \iota'_{n_s} Q_{sk}, \qquad D = \operatorname{diag}(a'_s \iota_{n_s})$$

which can again be computed even if the clusters are large. The estimate  $\hat{\Omega}$  replaces  $\sigma_{\epsilon}^2$  and  $\rho$  with analog estimates.
